

Nonlinear Expectations: Making Sense of Professional Forecasts*

Julio Ortiz [†]

September 2020

Abstract

Among professional forecasters, the same respondent simultaneously over- and underreacts to distinct macroeconomic variables. I show that these empirical patterns can arise in nonlinear environments, where rational forecasters are unable to obtain an optimal and exact estimate of the state via the Kalman filter. I consider stochastic volatility as the source of nonlinearities and assume that forecasters must approximate the state by selecting an approximation function from a set of costly alternatives. According to my model, over- and underreactions depend crucially on the underlying signal-to-noise ratio. In particular, the scope for overreactions is decreasing in the signal precision. I conclude that error predictability is not prima-facie evidence against rationality.

Keywords: Rational expectations. Noisy information. Forecasting. Stochastic volatility. Nonlinear filtering.

1 Introduction

Professional forecasts exhibit error predictability. While several theories have been devised to explain these apparent deviations from rationality, how to best model simultaneous over- and underreactions to different macroeconomic variables remains an open question. I show that one can successfully match this empirical fact by relaxing a restriction on how the latent state is allowed to evolve. Macroeconomic and financial time series have been found to exhibit complex dynamics such as stochastic volatility, structural breaks, and regime switching. At present, most models of expectations formation assume a linear environment. This provides the benefit of tractability, however, when taking the theoretical implications to the data, these models attribute error predictability to non-rational behavior.

Addressing this misspecification can make error predictability compatible with rationality. This is because nonlinear models no longer imply a simple analytical solution to the minimum mean square error estimate. Instead, to generate predictions forecasters must first approximate the nonlinear state. If there are costs to implementing approximation methods, then the choice of which approximation to use is not immediately obvious. Subject to such costs, forecasters can optimally adopt different approximation functions. As a result, revisions can hold predictive power over errors, and conventional efficiency tests would not necessarily detect non-rational behavior.

Survey data is predominantly used to test theories of expectation formation. In this paper, I make use of the Survey of Professional Forecasters (SPF) which provides a panel of multi-horizon forecasts across several macroeconomic variables. The literature has documented evidence of error predictability at both the forecaster- (individual) level as well as at the consensus- (aggregate) level across several surveys.¹ At the consensus-level, underreactions tend to prevail. Interestingly, at the forecaster-level there is evidence of coincident over- and underreactions among forecasters. I show how prevalent this phenomenon is by computing the share of forecasters that simultaneously overreact to one variable and underreact to another in the SPF.

Theories such as those of forecast smoothing and strategic complementarities have been offered to explain individual and aggregate underreaction. At the same time, models of diagnostic expectations and overconfidence can deliver individual overreaction and aggregate underreaction. A unified theory that accommodates

¹Examples other than the SPF include the Livingston survey, the Michigan Survey of Consumers, the NY Fed Survey of Consumer Expectations, Blue Chip forecasts, the ECB Survey of Professional Forecasters, and the daily Focus Survey from the Central Bank of Brazil, among others.

either behavior at the individual-level, however, is missing. Simultaneous over- and underreaction prompts several fundamental questions about expectations formation. Are professional forecasters (presumably the most informed private agents in the economy) rational? Does a behavioral bias govern the manner in which expectations are formed? As policymakers increasingly pursue expectations-based policies such as forward guidance, taking a step toward reconciling theories of expectations formation with the data is of first-order importance.

Against this backdrop, I present a nonlinear noisy information model. Specifically, stochastic volatility coupled with heterogeneity in use of approximation functions can replicate important features of the data. Rather than obtaining an exact solution to the optimal inference problem, forecasters must approximate the posterior distribution. They may choose from a finite set of approximation methods. The available methods vary in their level of sophistication, and adopting a given approximation function is subject to a random cost. These costs are increasing with the sophistication of the approximation. Forecasters generate a prediction that minimizes the sum of their mean squared errors and adoption costs. Importantly, forecasters in my adopt adopt simpler models for those macro variables that are easier to predict. This tends to make revisions smoother thereby raising the scope for underreaction. On the other hand, forecasters have an incentive to adopt more sophisticated predictor functions for complex macro variables. The resulting forecasts feature more volatile revisions which raise the scope for overreactions. In other words, overreactions tend to arise for variables characterized by lower signal-to-noise ratios.

I take a systematic approach to building this model by first generalizing a standard linear noisy information rational expectations model. This is done in order to incorporate a number of extensions such as a multivariate state as well as public and private signals. I focus on forecasts made about public signals because while forecasters formulate expectations about unobserved fundamentals, *they report predictions about public signals observed with a lag*. For instance, forecasters observe past inflation and formulate expectations conditional on their respective information sets. These inflation expectations are ultimately what forecasters report when surveyed. Assuming that inflation is a function of some unobserved state, then this variable is best modeled as a public signal. The flexible framework presented implies that one can no longer extract an estimate of information rigidity by merely projecting ex-post errors on ex-ante revisions. Furthermore, I verify that linearity and rationality jointly imply error orthogonality regardless of the generalizations made to state dynamics or signal structure.

After this, I modify the general model by incorporating time varying volatility into the state transition

equation. I show that deviating from the simple linear state space model can deliver error predictability among otherwise rational forecasters who face costs to adopting approximation functions. Such a model implies that current period forecasts can be expressed as a sum of the optimal minimum mean square error forecast and an approximation error. To extract additional intuition for the sources of over- and underreactions, I consider a stylized version of the model. For simplicity, I assume that forecasters can either approximate the state via a naive linear approximation that uses the Kalman filter, or via an asymptotically efficient approximation method (the particle filter). The latter approximation method is more costly than the former.² There are several motivations for modeling costs that increase with level of sophistication such as the cognitive cost to generating a forecast that uses a more complex approximation function. Alternatively, a more sophisticated approximation method may require additional computing time.

This stylized model is able to speak to the relation between errors and revisions at either level of aggregation. I find that the covariance between errors and revisions depends importantly on the data generating process. Put another way, there are certain features inherent to a given macroeconomic time series that explain why forecasters appear to either over- or underreact to that particular variable. Simulation results suggest that overreactions arise when the signal-to-noise ratio is low. On the other hand, when there is less noise characterizing the system, the model delivers underreactions.

I verify these implications in the data by exploiting the cross-section of macroeconomic variables for which forecasters report predictions in the SPF. In addition to this, I calibrate the stylized model for real GDP and the unemployment rate and find that the implied signal-to-noise ratio is consistent with the simulation results. Taken together, my findings suggest that error predictability is not sufficient to reject rationality in all contexts, but rather, it is evidence against *linear* rational expectations.

In their seminal paper, [Coibion and Gorodnichenko \(2015\)](#), henceforth CG, make sense of forecast error inefficiency while preserving the assumption of rationality. They do so by incorporating imperfect information into a standard linear rational expectations model. Using consensus-level data, CG show that projecting *ex-post* forecast errors on *ex-ante* forecast revisions delivers an estimate of information rigidity.

More recently, many studies have used forecaster-level data to test for rationality.³ In doing so, much of

²I have also experimented with a local linear approximation method such as the Extended Kalman filter, and the Unscented Kalman filter which makes use of specially chosen mass points. Though I do not provide an analytical result here, one could in principle expand the set of approximation functions arbitrarily by indexing an approximation function by the number of particles specified in a particle filter. I provide brief summaries on these methods in Appendix C.

³Examples include [Bordalo et. al \(2020\)](#), [Fuhrer \(2018\)](#), [Dovern et al. \(2015\)](#), [Andrade and Le Bihan \(2013\)](#), [Broer and Kohlhas \(2018\)](#), [Bürgi \(2016\)](#).

this literature preserves the linearity assumption made in CG, and ultimately rejects rational expectations even under imperfect information. Running the same regression as CG at the forecaster-level delivers non-zero point estimates for most macroeconomic variables. To make sense error predictability at the individual-level while also matching the CG finding of underreactions at the aggregate level, several theories of non-rational expectations have been proposed.⁴

Moreover, the model in this paper is in the spirit of Branch (2004), Evans and Ramey (1992) and Brock and Hommes (1997) who define adaptively rational equilibrium dynamics (ARED). Branch (2004) was the first to introduce this concept to expectations formation. This paper adds to those insights in key ways. First, I present more complex dynamics for the state variable. Introducing nonlinearities, such as stochastic volatility, provides a stronger justification for the use of different predictor (approximation) functions. Second, I allow for heterogenous expectations whereas Branch (2004) assumes homogeneous predictions among all who adopt a specific predictor function.⁵ Taken together, my model is able to reproduce the empirical facts that are present in survey data both at the individual and aggregate levels.

While a discussion of nonlinearities has generally been absent in the survey expectations literature, the finance literature has previously tied nonlinear dynamics to error predictability. For instance, Lewis (1989) considers error predictability concerning dollar forecasts in the context of a structural break. Veronesi (1999) finds that over- and underreactions arise in a regime switching model of asset pricing. More recently, Lansing et al. (2019) attribute the predictability of excess returns to either volatility or deviations from rationality. To this end, my paper also relates to the literature on volatility in macroeconomics. See for instance, Justiniano and Primiceri (2007), Kim and Nelson (1998), McConnell and Perez-Quiroz (2000), and Stock and Watson (2002). Finally, due to the assumptions imposed on the state dynamics, this paper relates to the literature on nonlinear filtering. Several approximation methods have been devised in order to deal with nonlinearities in the evolution of a state variable. These methods include generalizations to Kalman filtering as well as importance sampling algorithms, among others.⁶ A strand of this literature has recently formalized some basic efficiency properties of particle filtering.⁷

Below, Section 2 presents previously documented facts about error predictability at the forecaster and

⁴For instance Bordo et. al (2020) rule out rationality in favor of diagnostic expectations. Other studies such as Fuster et al. (2010) argue in favor of models featuring misperception at long horizons. Daniel et al. (2003) argues for a model of overconfidence while Broer and Kohlhas (2018) present a model of relative overconfidence.

⁵Heterogeneity in that model comes from idiosyncratic “trembles” in the reported prediction.

⁶Julier and Uhlman (2004) develop a Kalman filter for nonlinear settings while Doucet and Johansen (2009) discuss particle filtering methods.

⁷See Crisan and Doucet (2002) and Hu et al. (2011)

consensus levels, as well as a more novel fact on simultaneous over- and underreactions. Section 3, presents a generalization of the standard model of expectations formation in the literature. Here I show that linearity is at the heart of error orthogonality. Section 4 incorporates nonlinear dynamics into the generalized model. Section 5 provides simulation results on a stylized version of this model. Section 6 reports empirical evidence in favor of a nonlinear model. Section 7 parameterizes the stylized model, and Section 8 concludes.

2 Evidence from Survey Data

The SPF is a quarterly survey provided by the Federal Reserve Bank of Philadelphia. The survey began in 1968Q4 and provides forecasts from several forecasters across a number of macroeconomic variables including real GDP, inflation, and unemployment, over many horizons, h . The variables of interest in this paper are the forecast error and the forecast revision. To construct forecast errors from forecaster i about variable x , $FE_{t+h,t}^i = x_{t+h} - x_{t+h|t}^i$, I take the difference between the realized real-time value for x at $t + h$ and the forecaster's h -step ahead prediction generated at time t . This convention is in keeping with the literature as using final estimates reported by the Bureau of Economic Analysis several quarters into the future could reflect data revisions. To compute forecast revisions, I exploit the term structure of forecasts generated by the survey respondents. Specifically, $FR_{t,t-1}^i = x_{t+h|t}^i - x_{t+h|t-1}^i$. This requires making use of the h -step ahead forecasts formulated in periods t and $t - 1$. In other words, I consider the fixed horizon, h and take the difference between two adjacent forecasts.

CG present the following testable implication at the consensus-level which holds for an arbitrary horizon, h

$$FE_{t+h,t} = \alpha_0 + \alpha_1 FR_{t+h,t} + \epsilon_t \quad (1)$$

CG find that in the data, $\alpha_1 > 0$ for most variables which indicates that consensus forecasts underreact to new information. The gradual adjustment of expectations that arises from the optimal filtering of noisy signals leads to the inertia in expectations formation.

More recently, [Bordalo et. al \(2020\)](#) estimate the same regression at the forecaster-level:

$$FE_{t+h,t}^i = \beta_0 + \beta_1 FR_{t+h,t}^i + \varepsilon_t^i \quad (2)$$

They find that $\beta_1 < 0$ for most macroeconomic series. The interpretation is that forecasters overreact to new

Table 1: Pooled OLS Forecast Error Predictability Regressions

	Nowcast		One-Quarter Ahead		Two-Quarters Ahead	
	β_1	α_1	β_1	α_1	β_1	α_1
Estimate	-0.317*** (0.050)	0.569*** (0.128)	-0.231** (0.067)	1.011*** (0.201)	-0.344*** (0.058)	0.565** (0.272)
Observations	65,070	2,323	54,067	2,309	52,220	2,295

Note: The table reports the estimated coefficients of forecast error predictability at the current, one-, and two-quarter ahead horizons. Across all horizons, column (1), refers to the forecaster-level errors-on-revisions regression. Column (2) refers to the consensus-level errors-on-revisions regression. Standard errors for forecaster-level regressions are as in Driscoll and Kraay (1998), while Newey-West standard errors are used for aggregate-level specifications. Data used for estimation come from SPF. *** denotes 1% significance, ** denotes 5% significance, and * denotes 10% significance.

information. [Bordalo et al. \(2020\)](#) explain these empirical findings with a model of diagnostic expectations wherein agents place more weight on recent developments as they believe these to be more representative of the objective probability distribution.

Table 1 reports estimates of β_1 and α_1 , using data from the SPF. The estimates are obtained via OLS regressions, pooling across both forecasters and macroeconomic variables. Estimates are reported for three different horizons. Across all horizons considered, it is clear that overreactions dominate at the individual-level, while underreactions arise at the aggregate-level.

In Table 2, I focus on the nowcast ($h = 0$), and estimate each testable implication variable-by-variable. The results point to individual overreactions for most variables (consistent with [Bordalo et al. \(2020\)](#)), although error orthogonality cannot be rejected for some variables. Furthermore, unemployment exhibits underreactions at the individual-level. At the consensus-level, underreactions dominate, however, real consumption and real government spending (both federal and state/local) feature no error predictability.

Whereas these empirical facts can arise due to non-rational biases, existing theories struggle to explain why a forecaster might simultaneously overreact to one variable and underreact to another. To get a sense of how common such an occurrence is, I estimate regression (2) for each forecaster i forecasting a specific variable j . This delivers an $N_i \times N_j$ matrix of estimates $\hat{\beta}_{1,ij}$. I keep only those estimates that are significant at 5% level. I then fix a pair of SPF variables j and k , and compute the number of forecasters such that $\hat{\beta}_{1,ij} < 0$ and $\hat{\beta}_{1,ik} > 0$. Finally, I count the number of forecasters for whom this condition holds and normalize by the number of total forecasters reporting predictions about variables j and k . More formally, I

Table 2: Pooled OLS Regressions at $h = 0$, by Variable

Note: The table reports the OLS coefficients from errors-on-revisions regressions across 15 macroeconomic variables reported in the Survey of Professional Forecasters. Column (3) reports the coefficient in front of the revision at the forecaster-level while column (4) reports the analogous coefficient using consensus-level data. The errors and revisions are for current period forecasts ($h = 0$). *** denotes 1% significance, ** denotes 5% significance, and * denotes 10% significance.

estimate a matrix P whose elements are p_{jk} with

$$p_{jk} = \frac{\sum_i \mathbb{1}(\hat{\beta}_{1,ij} < 0 \text{ and } \hat{\beta}_{1,ik} > 0)}{\min\{N_j, N_k\}}$$

where N_x denotes the number of forecasters providing predictions of variable x and $\mathbb{1}(\cdot)$ is the indicator function. The elements of matrix P , therefore, tell us the share of forecasters who simultaneously overreact to the row variable and underreact to the column variable. When p_{jk} is close to one, this means that nearly all forecasters overreact to variable j and underreact to variable k . On the other hand, when p_{jk} is close to zero, then almost no forecaster overreacts to variable j while also underreacting to variable k .

Figure 1 reports the results from this exercise. The figure verifies that a given forecaster tends to overreact to some variables and underreact to others. This is particularly pronounced when considering overreactions to real variables. For instance, 84% of professional forecasters exhibit overreactions when forecasting real gross domestic product (RGDP) while simultaneously underreacting to their predictions about consumer prices (CPI). Moreover, it is less common for forecasters to overreact to financial variables as evidenced by the lighter shades for the 3-month treasury bills (TBILL) and 10-year bonds (TBOND) rows. In order

Figure 1: Frequency of Over- and Underreaction by the Same Forecaster

Note: This figure displays the share of forecasters who overreact to the row variable and simultaneously underreact to the column variable.

to understand how individuals formulate their predictions of the future, a theory of expectations formation must take into account that a single agent may overreact and underreact to different variables.

3 Generalized Linear Baseline Model

Before presenting the nonlinear model, I generalize the standard model in the literature and provide some analytical results about error predictability. Consider a linear Gaussian state space model. Suppose there are

n latent state variables and m exogenous signals.

$$\begin{aligned} \mathbf{s}_t &= \mathbf{A}\mathbf{s}_{t-1} + \mathbf{B}\mathbf{w}_t \\ \mathbf{z}_t^i &= \mathbf{C}\mathbf{s}_t + \mathbf{D}\mathbf{v}_t^i \end{aligned} \tag{3}$$

Note that \mathbf{s}_t is an $n \times 1$ vector, \mathbf{A} is $n \times n$, \mathbf{B} is $n \times n$ and \mathbf{w}_t is $n \times 1$. Furthermore, \mathbf{z}_t is $m \times 1$, \mathbf{C} is $m \times n$, \mathbf{D} is $m \times m$ and \mathbf{v}_t^i is $m \times 1$. There are no other restrictions placed on the model. In particular, \mathbf{s}_t can be a vector of many different state variables, or lags of itself. \mathbf{B} need not be a diagonal matrix. Furthermore, \mathbf{z}_t^i can include an arbitrary finite number of observed signals. The noise vector \mathbf{v}_t^i can include private or public noise.⁸

From the Kalman filter, the optimal state estimate is defined as

$$\mathbf{s}_{t|t}^i = \mathbf{s}_{t|t-1}^i + \kappa(\mathbf{z}_t^i - \mathbf{z}_{t|t-1}^i) \tag{4}$$

where κ is the (constant) Kalman gain. Since the state is unobservable, forecasters can only formulate predictions of the signals and assess the mistakes made with regard to these observables. The optimal forecast of the signal vector \mathbf{z}_t^i is

$$\mathbf{z}_{t+1|t}^i = \mathbf{z}_{t+1|t-1}^i + \mathbf{C}\mathbf{A}\kappa(\mathbf{z}_t^i - \mathbf{z}_{t|t-1}^i) \tag{5}$$

Forecast errors for the generalized linear model can be expressed as follows

$$\mathbf{z}_{t+1}^i - \mathbf{z}_{t+1|t}^i = (\mathbf{z}_{t+1}^i - \mathbf{z}_{t+1|t-1}^i) - \mathbf{C}\mathbf{A}\kappa(\mathbf{z}_t^i - \mathbf{z}_{t|t-1}^i) \tag{6}$$

Furthermore, the forecast revision is

$$\mathbf{z}_{t+1|t}^i - \mathbf{z}_{t+1|t-1}^i = \mathbf{C}\mathbf{A}\kappa(\mathbf{z}_t^i - \mathbf{z}_{t|t-1}^i) \tag{7}$$

Using these expressions, one can derive the two testable implications presented in the previous section.

Proposition 1. *The generalized linear model implies the following:*

(i) $\beta_1 = 0$

⁸I index this vector by i in general to allow for forecaster-specific signals.

$$(ii) \alpha_1 = \mathbf{CA}(\mathbf{I} - \mathbf{C}\kappa)(\kappa\mathbf{C})^{-1}(\mathbf{CA})^{-1} > 0$$

Proof. See Appendix A. □

The proofs are straightforward and detailed in Appendix A: (a) holds given the orthogonality condition that must be satisfied at the individual-level under rational expectations. Forecast error orthogonality implies that $\mathbb{E}[(\mathbf{z}_t^i - \mathbf{z}_{t|t}^i)\mu] = \mathbf{0}$ for any μ residing in the forecaster's information set.⁹ Put another way, rationality implies the optimal use of information so that no variable residing in one's information set may predict the forecast error. This very general model precludes the predictability of forecast errors at the individual-level. As a result, any such linear Gaussian model with mean square loss cannot generate error predictability, regardless of the signal structure.

Moreover, (b) is a generalization of the CG result. The extent to which the mean revision predicts mean errors is determined by the Kalman gain matrix and the matrix \mathbf{C} which maps the underlying state to the observed signal vector. The generalized linear model nests the CG result. Letting $\mathbf{C} = 1$, $\mathbf{D} = \sigma_v$, $\mathbf{A} = \rho$ and $\mathbf{B} = \sigma_w$, it follows that $\alpha_1 = \frac{1-\kappa}{\kappa}$. In this limiting case, one can recover an estimate of information rigidity by projecting consensus errors on consensus revisions. Importantly, the signal structure must be such that $\mathbf{C} = 1$. If, instead, the elements of \mathbf{C} include additional parameters, or there is common noise in the signal vector, then it is no longer possible to cleanly extract the Kalman gain from a standard OLS regression.¹⁰

4 A Model of Heterogeneous Rational Approximations

A nonlinearity such as time-varying volatility complicates the problem as forecasters must now formulate expectations about the level and the volatility of the underlying state.

4.1 Nonlinear Filtering Problem

To this end, I do away with the linearity assumption made in Section 3 and instead suppose that the volatility of the state varies over time. This requires modifying the covariance matrix of innovations: $\mathbf{B} \rightarrow \mathbf{B}_t$. One

⁹Similarly, there is a revision orthogonality condition implied by rationality which states that $\mathbb{E}(\mathbf{z}_{t|t}^i - \mathbf{z}_{t|t-1}^i | \mathcal{I}_t^i) = 0$. See Pesaran and Weale (2006).

¹⁰See CG for a discussion of the bias in estimated information rigidities induced by public noise.

can generally formulate the model as follows:

$$\begin{aligned}\bar{\mathbf{s}}_t &= F(\bar{\mathbf{s}}_{t-1}, \bar{\mathbf{w}}_t) \\ \mathbf{z}_t^i &= \mathbf{C}\bar{\mathbf{s}}_t + \mathbf{D}\mathbf{v}_t^i\end{aligned}\tag{8}$$

The crucial difference between the linear model and this one is the expanded state space: $\bar{\mathbf{s}} = [\mathbf{s}_t \quad \text{diag}(\mathbf{B}_t)]^\top$. This implies that the state is no longer linear as the error now enters multiplicatively into the state. This non-linearity is modeled by the function $F(\cdot)$ which governs the evolution of the state. While the state now exhibits stochastic volatility, the shocks remain normal, and the signal structure is unchanged. Hence, the measurement equation remains linear.^{11 12}

Whereas Kalman filtering delivers an exact optimal solution in a linear Gaussian environment, it is no longer optimal in this context. The reason for this is that the Kalman filter requires one to evaluate the expected value of $\bar{\mathbf{s}}_t$ conditional on the history of signals $\mathcal{Z}_t^i = \{\mathbf{z}_1^i, \dots, \mathbf{z}_t^i\}$. This is made intractable due to the lack of knowledge about the underlying conditional distribution. To see this more clearly, consider the scalar case where the state is s_t and there is only a private signal available to the forecaster, z_t^i . The observation equation can be expressed as a conditional likelihood, $p(z_t^i|s_t)$ and the state evolution as $p(s_{t+1}|s_t)$. The optimal filter computes $p(s_t|\mathcal{Z}_t^i)$ from a predict-update procedure:

$$\begin{aligned}p(s_t|\mathcal{Z}_{t-1}^i) &= \int p(s_t|s_{t-1})p(s_{t-1}|\mathcal{Z}_{t-1}^i)ds_{t-1} \quad (\text{Predict}) \\ p(s_t|\mathcal{Z}_t^i) &= \frac{p(z_t^i|s_t)p(s_t|\mathcal{Z}_{t-1}^i)}{p(z_t^i|\mathcal{Z}_{t-1}^i)} \quad (\text{Update})\end{aligned}$$

where $p(z_t|Z_{t-1}^i) = \int p(z_t^i|s_t)p(s_t|Z_{t-1}^i)ds_t$.

In a linear Gaussian environment, this can be exactly computed via the Kalman recursions.¹³ In a non-linear setting, however, computing $p(s_t|\mathcal{Z}_t^i)$ is not feasible as the density cannot be obtained analytically.

In light of this, forecasters must approximate the nonlinear state. I assume that this is done by selecting from a set of costly approximation functions ($A \in \mathcal{A}$). Forecasters first select an approximation function so as to obtain an estimate of the posterior density of the underlying state. Forecasters then report their

¹¹This could be generalized to a nonlinear measurement as well. I abstract away from this for simplicity.

¹²While I consider stochastic volatility, any nonlinearity can deliver the results presented in the paper. In particular, this model can also speak to unobserved changes in the persistence of macroeconomic time series.

¹³ $p(s_t|\mathcal{Z}_t^i) \sim \mathcal{N}(s_{t|t}^i, \Psi_{t|t}^i)$, where $s_{t|t}^i$ is the expected value of the posterior density and $\Psi_{t|t}^i$ is the variance.

predictions (i.e. first moment of this approximated density). Hence, the forecaster's loss function can be defined as

$$\mathcal{L} = \min_{A \in \mathcal{A}} \left\{ (\mathbf{z}_{t+h}^i - \hat{\mathbf{z}}_{t+h|t}^{i,A})^\top (\mathbf{z}_{t+h}^i - \hat{\mathbf{z}}_{t+h|t}^{i,A}) + (c_A^i)^2 \right\} \quad (9)$$

where the first term is the mean square error arising from individual i 's forecast which makes use of approximation function A , and the second term denotes the cost associated with adopting approximation function A .¹⁴ In order to obtain heterogeneity in adoption of approximation functions, I assume that these costs are drawn randomly $c_A^i \sim U(0, \bar{c}_A)$.¹⁵

4.2 Approximate Predictions

After applying either of the approximation methods discussed, forecasters generate a prediction of the state and an update according to the new information received. Since agents are formulating a forecast subject to an approximation of the state, I call these approximate predictions. An approximate prediction is defined as

$$\hat{\mathbf{s}}_{t|t}^i = \int \bar{\mathbf{s}}_t \hat{p}(\bar{\mathbf{s}}_t | \mathcal{Z}_t^i) d\bar{\mathbf{s}}_t \quad (10)$$

In essence, the forecaster predicts the current state according to the approximated density $\hat{p}(\bar{\mathbf{s}}_t | \mathcal{Z}_t^i)$. In a linear Gaussian setting, the density is obtained exactly so that $\hat{p}(\bar{\mathbf{s}}_t | \mathcal{Z}_t^i) = p(\bar{\mathbf{s}}_t | \mathcal{Z}_t^i)$ and errors are orthogonal.

Moreover, from definition (10), one can express the approximate prediction as a deviation from the optimal minimum mean square error forecast. More specifically, the approximate prediction of a model with a nonlinear state evolution and a linear Gaussian measurement can be expressed as

$$\hat{\mathbf{s}}_{t|t}^i = \underbrace{\mathbb{E}(\bar{\mathbf{s}}_t | \mathcal{Z}_t^i)}_{\text{Optimal}} + \underbrace{\int \bar{\mathbf{s}}_t [\hat{p}(\bar{\mathbf{s}}_t | \mathcal{Z}_t^i) - p(\bar{\mathbf{s}}_t | \mathcal{Z}_t^i)] d\bar{\mathbf{s}}_t}_{\text{Approximation error}} \quad (11)$$

To understand how approximation errors might generate over- and underreactions to different macroeconomic variables, note that there is no restriction imposed on the sign of these mistakes. Furthermore, forecast error predictability is entirely explained by predictability of approximation errors. Whereas existing theories

¹⁴Forecasters have knowledge of the mean square error associated with each A .

¹⁵One could alternatively assume heterogeneous signal precision. Models featuring heterogeneous signal-to-noise ratios have been proposed in the literature, particularly to explain forecast disagreement.

of expectation formation restrict the deviation from the optimal forecast to be either positive (overreactions) or negative (underreactions), the direction of the approximation error is unrestricted.

From the nonlinear model subject to approximation errors, the covariance of errors and revision can be signed as follows:

$$\begin{aligned} \beta_1 \propto \mathbb{C} \left(\bar{s}_t, \int \bar{s}_t [\hat{p}(\bar{s}_t | \mathcal{Z}_t^i) - \hat{p}(\bar{s}_t | \mathcal{Z}_{t-1}^i)] d\bar{s}_t \right) \\ - \mathbb{C} \left(\int \bar{s}_t \hat{p}(\bar{s}_t | \mathcal{Z}_t^i) d\bar{s}_t, \int \bar{s}_t [\hat{p}(\bar{s}_t | \mathcal{Z}_t^i) - \hat{p}(\bar{s}_t | \mathcal{Z}_{t-1}^i)] d\bar{s}_t \right) \end{aligned}$$

Note that when there are no approximation errors, error orthogonality holds and $\beta_1 = 0$. In the case of non-zero approximation errors, however, the first term is the source of observed underreaction while the second term governs the extent of overreaction. It worth noting that the quality of an approximate prediction does not affect β_1 in a trivial manner. Instead, the way in which forecasters update their approximate predictions informs whether β_1 is positive or negative.

When forecast revisions are more closely related to the underlying state, then underreactions arise as the first term dominates the second. If instead, forecast revisions covary more with the current prediction than the underlying state, then overreactions result. In essence, when the approximate revision incorporates more noise than is optimally called for, then forecasters will appear to overreact.

4.3 A Simple Example

Suppose that the state is described as follows

$$\begin{aligned} s_t &= \rho s_{t-1} + \sigma_t w_t, & w_t &\sim \mathcal{N}(0, \sigma_w^2) \\ \sigma_t &= \chi \sigma_L + (1 - \chi) \sigma_H \end{aligned}$$

where $\chi = 1$ with probability q and $\chi = 0$ with probability $1 - q$. Forecasters receive private signals $y_t^i = s_t + v_t^i$ each period, where $v_t^i \stackrel{i.i.d.}{\sim} \mathcal{N}(0, \sigma_v^2)$. Forecasters do not know the value of s_t or q , and can only observe the sequence of private signals $\{y_k^i\}_{k=0}^t$.¹⁶

To see how overreactions arise, suppose that forecasters assess the volatility of the state to be $\sigma_t =$

¹⁶The assumption that forecasters are unable to observe q is for simplicity. Alternatively, one could suppose that the probability is stochastic ($q + \epsilon$) and that forecasters cannot observe the innovation ϵ .

$\frac{1}{2}(\sigma_L + \sigma_H)$, and forecast according to the Kalman filter subject to this naive approximation of the underlying state volatility. When q is closer to one, the signal-to-noise ratio is low and forecasters believe the state to be more variable than it truly is. As a result, forecasters place a larger weight on new information. This undue importance to news will generate overreactions. According to this simple example, the magnitude of the overreaction depends importantly on the signal-to-noise ratio. Noisier environments deliver more negative β_1 coefficients.

On the other hand, an underreaction could arise under slightly different dynamics. One can verify this by simply allowing q to be closer to zero so that the signal-to-noise ratio rises. Now, when forecasters generate approximations, they believe the state to be less variable than it truly is thereby placing less weight on news. This mutes the effects of signal noise and creates more inertia in expectation formation than is optimal. The result is, $\beta_1 > 0$.

Though this is another very simple case, it illustrates how a different approximation strategy can deliver underreactions. In particular, this updating procedure delivers smoother revisions. Moreover, the extent of observed underreaction is increasing in the variance of the state. If forecasters could simply observe q , however, then there would be no need to approximate the variance of the state and error orthogonality would hold. Of course, a naive approximation will deliver a bias in predictions. However, when approximation functions come at a cost (be it cognitive, timing, or otherwise), forecasters may find it optimal to make use of such approximations. Figure 2 below plots simulated errors against simulated revisions for each of these examples. The left panel shows that overreactions prevail when the revision is noisier whereas underreactions are observed when revisions are smoother.

4.4 Aggregate Error Predictability

Similar to the approximate prediction defined above, the consensus forecast arising from approximate predictions is defined as follows

$$\begin{aligned} \alpha_1 \propto \mathbb{C} \left(\bar{s}_t, \int \int \bar{s}_t \left[\hat{p}(\bar{s}_t | Z_t^i) - \hat{p}(\bar{s}_t | Z_{t-1}^i) \right] d\bar{s}_t di \right) \\ - \mathbb{C} \left(\int \int \bar{s}_t \hat{p}(\bar{s}_t | Z_t^i) d\bar{s}_t di, \int \int \bar{s}_t \left[\hat{p}(\bar{s}_t | Z_t^i) - \hat{p}(\bar{s}_t | Z_{t-1}^i) \right] d\bar{s}_t di \right) \end{aligned}$$

In the previous subsection, it was determined that more volatile revisions increase the scope for over-

Figure 2: Volatility-Generated Overreactions and Underreactions

Note: The figures display simulated scatters plots from the examples described in the text. The panel titled “Over-reaction” assumes that $q = 0.80$ while the panel titled “Under-reaction” supposes that $q = 0.20$. The simulation is done by specifying one single forecaster for 10,000 periods, and fixing the approximation $\hat{\sigma}_t = \frac{1}{2}(\sigma_L + \sigma_H)$

reaction. Upon aggregating (symmetrically) across several individual forecasts, the consensus revision will exhibit more persistence than the individual revisions. This motivates the next result

Proposition 2. *In the nonlinear noisy information model, $\alpha_1 \geq \beta_1$.*

Proof. See Appendix A. □

The model implies that the OLS coefficient estimated from an errors on revisions regression will be weakly greater than the analogous coefficient obtained from a pooled regression of individual forecasters. This result does depend on the presence of nonlinear dynamics. In fact, this holds in the linear setting as well (see Proposition 1).¹⁷

¹⁷This need not be the case in other economic settings in which agents take actions, and their decisions are aggregated in a manner other than by taking a simple mean. Depending on the context, it is possible for the aggregate decision to also exhibit overreaction or excess volatility. [Bordalo et. al \(2020\)](#) provide a discussion of this.

4.5 Relation to Some Theories of Expectation Formation

Several other theories of expectations formation have been proposed in the literature. Here, I consider a few prominent theories and assess their ability to generate the empirical facts presented in Section 2.

Diagnostic Expectations

According to diagnostic expectations, forecasters over-weight new information according to a parameter $\theta > 0$ which governs the extent of overreactions. This parameter comes from the representativeness heuristic of [Kahneman and Tversky \(1974\)](#). The diagnostic nowcast is defined as $x_{t|t}^{i,\theta} = x_{t|t}^i + \theta(x_{t|t}^i - x_{t|t-1}^i)$. This theory makes use of a distorted Kalman filter called the diagnostic Kalman filter. Nonetheless, as shown in [Bordalo et. al \(2020\)](#), diagnostic expectations are able to generate $\beta_1 < 0$ and $\alpha_1 > 0$. One shortcoming of this theory is that it is unable to explain individual underreaction ($\beta_1 > 0$). While the majority of macroeconomic time series can be characterized by overreactions at the forecaster-level, some such as unemployment, robustly exhibit underreaction at the individual level. Because $\theta > 0$, this theory cannot generate such underreaction. In other words, diagnostic expectations imply that errors and revisions always covary negatively due to the sign restriction imposed on θ .

Overconfidence

Models of overconfidence also distort the Kalman gain. The distortion stemming from overconfidence, however, is different. According to this theory, forecasters misperceive the precision of their own signals. Suppose that forecasters observe only one private signal, $z_t^i = s_t + v_t^i$ with $v_t^i \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma_v^2)$. Then, forecasters perceive $\tilde{\sigma}_v < \sigma_v$ (they believe their own private signals to be more precise than they truly are). This results in a distorted signal-to-noise ratio that forecasters use when computing their filtered estimates. Overconfident beliefs are recursive so that the distorted gain injects a bias to the update in each period. These beliefs are then projected forward only to be further distorted by the over-weighting of new information in the subsequent period. In other words, the use of $\tilde{\kappa}$ (which is larger than the optimal gain, κ) compounds so that at an arbitrary point in time, forecasters exhibit both a non-zero ex-ante forecast error as well as a weighting error. Models of overconfidence can generate individual overreaction as well as aggregate underreaction, however, this model is similarly unable to generate individual underreaction.

Strategic Interaction

Strategic interaction models can also generate error predictability. For instance, models of strategic substitution can drive errors and revisions in opposite directions. This is because forecasters have a dual objective of not only minimizing their errors but also of distinguishing themselves from the average forecast. These models differ from the previous two in that strategic interaction models are rational. The reported forecast can also be expressed as deviation from the optimal forecast. The deviation is a function of the degree of strategic substitutability (complementarity) and the deviation of the optimal forecast from the consensus forecast. While this class of models can generate $\beta_1 > 0$ or $\beta_1 < 0$ depending on the strategic motive assumed, it is unable to jointly deliver $\beta_1 > 0$ and $\beta_1 < 0$.

Noisy Memory

More recently, a model of noisy memory was introduced in [Azeredo da Silveira and Woodford \(2019\)](#). In a noisy memory model, forecasters do not have access to their full history of signals due to finite memory capacity. The authors find that while rational inattention can explain individual underreactions, noisy memory may explain individual overreactions. From this model, however, it is not immediately obvious how aggregate underreactions could arise when all forecasters overreact. It also does not directly explain why the same forecaster might overreact and simultaneously underreact to different variables.¹⁸ Lastly, the notion of forgetting past information, while compelling in general, is difficult to fathom among professional forecasters who can presumably store past forecasts and new information with relative ease.

Several other theories of expectations formation have been found to be inconsistent with the data. Models of reputational concerns imply smoothing which can only generate $\beta_1 > 0$. Moreover, asymmetric loss functions deliver counterfactually biased expectations, whereas the data show that professional forecasts are not unconditionally biased.

5 A Stylized Model of Heterogeneous Rational Approximations

To extract further insight as to how time-varying volatility can generate observed overreactions, I consider next a simple model of stochastic volatility in which forecasters select an approximation procedure. Let the

¹⁸On both of these points, developing a hybrid rational inattention-noisy memory model could be a promising endeavor.

underlying state be described as follows:

$$s_t = \rho s_{t-1} + e^{h_t/2} w_t, \quad w_t \sim \mathcal{N}(0, 1) \quad (12)$$

$$h_t = \phi_0 + \phi_1 h_{t-1} + \sigma_\eta \eta_t, \quad \eta_t \sim \mathcal{N}(0, 1)$$

Furthermore, forecasters observe a contemporaneous private signal as well as a lagged public signal ¹⁹

$$\begin{aligned} y_t^i &= s_t + v_t^i, & v_t^i &\stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma_v^2) \\ x_{t-1} &= s_{t-1} + e_{t-1}, & e_{t-1} &\sim \mathcal{N}(0, \sigma_e^2) \end{aligned} \quad (13)$$

The specific assumptions on the volatility of s_t implies that this model is nonlinear. In addition to being unable to observe s_t , forecasters are also unable to observe h_t . As such, the innovation w_t now enters into the state multiplicatively. Moreover, let $\mathbf{z}_t^i = [y_t^i \quad x_{t-1}]^\top$ denote the vector of signals observed by forecasters.

Each period consists of two stages. In the first stage, a forecaster observes \mathbf{z}_t^i and selects an approximation function from a finite set $A \in \mathcal{A}$. For simplicity, define $\mathcal{A} = \{A_{KF}, A_{PF}\}$. The forecaster must pay a cost for using any A . Then in the second stage, given the approximation function and the history of signals \mathcal{Z}_t^i , the forecaster reports a prediction of the public signal $\hat{x}_{t|t}^i$.²⁰ For simplicity, I normalize $\bar{c}_{KF} = 0$. With this in mind, forecasters minimize the following loss function:

$$\mathcal{L} = \min \left\{ MSE_{KF}, MSE_{PF} + (c_{PF}^i)^2 \right\}$$

a forecaster will choose to make use of the more sophisticated PF if and only if

$$MSE_{KF} - MSE_{PF} \geq (c_{PF}^i)^2 \quad (14)$$

The lefthand side of the inequality reflects the benefit to adopting the PF when formulating a prediction whereas the righthand side denotes the relative cost to adopting the PF.

This basic model belongs to the class of models described in the previous section. Importantly, this model

¹⁹One can alternatively envision that forecasters observe a macroeconomic variable with a transitory (e_t) and persistent (s_t) component. The persistent component is what is relevant for forecasting the target variable as it governs the long-run evolution of the random variable. Furthermore, this component is unobserved.

²⁰At t , forecasters make use of their full history of signals in order to formulate a state estimate, $\hat{\mathbf{s}}_{t|t}^i$. The first element of the forecasted state vector is $\hat{s}_{t|t}^i$. Based on the assumption that $x_t = s_t + e_t$, it follows that $\hat{x}_{t|t}^i = \hat{s}_{t|t}^i$.

Table 3: Signal-to-Noise Ratio and Implied OLS Coefficients

Individual	Aggregate	SNR	β_1	α_1
Underreaction	Underreaction	1.427	0.12	0.46
Overreaction	Underreaction	0.433	-0.14	0.18

Note: The table simulates the errors-on-revision coefficient at the forecaster-level (β_1) and the consensus-level (α_1) for two different simulated signal-to-noise ratios. I simulate a panel of 40 forecasters over 200 periods (of which the first 100 periods are discarded). Each simulated forecaster generates a prediction according to the model. I then run a pooled regression for 2,000 simulated panels and report the mean point estimate.

is based on the principle that forecasters remain rational in the sense that they exhibit optimizing behavior.

Clearly, $\beta_1 \neq 0$ in general. To better understand the sign of β_1 , consider again the definition from Section 4.

$$\beta_1 \propto \underbrace{\mathbb{C}(s_t, \hat{x}_{t|t}^i - \hat{x}_{t|t-1}^i)}_{\text{Underreaction}} - \underbrace{\mathbb{C}(\hat{x}_{t|t}^i, \hat{x}_{t|t}^i - \hat{x}_{t|t-1}^i)}_{\text{Overreaction}}$$

This is simply the definition of the covariance between forecast errors and forecast revision. The OLS coefficient is proportional to two terms, each illustrating a particular channel through which overreaction/underreaction arises. I call the first term the underreaction channel. The extent to which the forecast revision covaries with the realized state drives the scope for underreaction in the model. The second term defines the overreaction channel. The strength of overreactions ultimately comes from the extent to which it revision covary with the nowcast (above and beyond the extent to which it covaries with the state). With this in mind, it follows that β_1 depends on the underlying amount of noise in the model. Fundamentally this is a noisy information environment in which forecasters infer the state subject to private and public signals. It stands to reason that as the signal-to-noise ratio (SNR) falls, forecast revisions are driven by the noise in the system. In this case, it is *as if* forecasters report their predictions with measurement error since an upward revision in the reported forecast will mechanically result in a more negative forecast error. On the other hand, when the SNR is high, then fluctuations in the underlying state drive the forecast revisions. As a result, an upward revision delivers a more positive forecast error.

It can be shown that the model is able to generate different signs for β_1 and α_1 depending on the parameter values. The parameters defining the state and measurement are $\{\rho, \sigma_e, \sigma_v, \phi_0, \phi_1, \sigma_\eta\}$. From the intuition described above, it follows that greater signal noise variances will generate overreactions. Moreover, greater state variability reduces the scope for overreaction.

The simulation results reported in Table 3 confirm that the nonlinear model is able to jointly explain

Figure 3: Covariance of Errors and Revisions Depends on Driving Process

Note: The figure plots two simulated densities of β_1 arising from a pooled individual-level errors-on-revisions regression from the model described in Section 5. The red dashed line plots the simulation in which private signal noise variance is relatively high whereas the solid blue line plots the simulation in which private signal noise variance is relatively low.

the patterns observed in the data. Consider the difference in parameter values between models of individual underreactions and models of individual overreactions. In order to flip the sign of β_1 from $\beta_1 > 0$ to $\beta_1 < 0$, I reduce the SNR from 1.43 to 0.43.²¹ These simulations suggest that observed under- and overreactions at the individual level can be explained by different underlying data generating processes among otherwise rational forecasters.

I next plot the simulated β_1 distribution across high signal-to-noise ratio and low signal-to-noise ratio parameterizations. For each of 2,000 simulations, I generate a panel of 40 forecasters over 200 periods (of which the first 100 periods are discarded). I then collect the nowcast errors and revisions for these forecasters and compute β_1 . Figure 3 plots the density of β_1 across the simulations. The results confirm that over- and underreactions depend on the SNR.

²¹ Although robust and reliable estimates of the SNR are missing in this literature, CG provide some estimates using cross-country data which are in line with the simulated SNR values here. In addition, these simulated SNR values are similar in magnitude to those that I estimate in Section 7.

6 Evidence from the Survey of Professional Forecasters

The intuition developed in Section 5 delivers model predictions that can be taken to the data. This section exploits the variation across the macroeconomic variables reported in the SPF. Each of the variables is presumed to follow a specific data generating process. As a result, $\beta_1 = \beta_1(\rho, \sigma_v, \sigma_e, \phi_0, \phi_1, \sigma_\eta)$ will, in general, vary in the cross-section of SPF variables.

Testable Prediction 1: Error Predictability and Private Noise

In this model, forecasters revise their predictions according to the realization of the lagged public signal as well as their contemporaneous private signal. The private signal noise therefore feeds into the forecast revision. From the perspective of the model, the variance of private signal noise determines the amount of dispersion in revisions across forecasters. More dispersed signal noise admits more pronounced differences in revisions.

With this insight, I collect the different β_1 coefficients across SPF variables and compute the interquartile range of revisions across forecasters for each variable. Figure 4 plots the results. As the model suggests, variables exhibiting greater dispersion in revisions tend to be those for which forecasters overreact.

Testable Implication 2: Error Predictability and Public Noise

While Figure 4 relates β_1 to private signal noise, there is also common noise present in the model. I next turn to measure the noisiness of the public signal. To reiterate, while the SPF variable of interest has sometimes been modeled as the latent state in the literature, it is best thought of as a lagged public signal. This is because the SPF variables are observed by all forecasters with a lag. With this in mind, the official government revisions made to these variables across different vintages can provide a measure of public signal noise. Assuming that the vintages following the initial real-time release of the variable eliminate some of the common noise, one can quantify these revisions over time. As a matter of notation, define x_t^0 as the real-time data release for a given variable, and x_t^L as the last release of the variable. Then, we can define $\text{noise}_t^{\text{public}} = x_t^0 - x_t^L$. I construct this variable from the first and last data vintage for all SPF variables in my sample, and then measure the dispersion of this public noise over time. Figure 5 relates β_1 with this measure of public signal noise. The results are consistent with the intuition of the model: variables exhibiting higher measured noise dispersion tend to deliver observed overreactions.

Figure 4: Error Predictability and Revision Dispersion

Note: For each SPF variable, the figure plots the estimated errors-on-revisions coefficient at the forecaster-level against estimated private noise dispersion, proxied by the interquartile range of forecast revisions. Slope of fitted line is -0.045 .

Testable Prediction 3: Error Predictability and Unconditional Volatility

Moreover, the model predicts that with more unconditional variability in the state, there is less scope for overreaction. To test this, I proceed to estimate ϕ_0 for each SPF variable. I then construct an estimate of unconditional volatility of the state ²²

$$\text{vol}_j = \exp\left(\frac{\hat{\phi}_0}{2}\right)$$

Figure 6 relates β_1 to vol_j . The figure supports the hypothesis that variables exhibiting more variability in the state tend to provide greater scope for underreactions. Furthermore, note that the variance of the state is increasing in ρ . Hence, the model predicts that more persistent variables will reduce the scope for overreactions. This is consistent with [Bordalo et. al \(2020\)](#) who verify this empirically.

²²I estimate the parameters of the stochastic volatility model, $\{\phi_0, \phi_1, \sigma_\eta\}$ using MCMC techniques (see Kastner and Fruhwirth-Schattner (2014)).

Figure 5: Error Predictability and Public Noise

Note: For each SPF variable, the figure plots the estimated errors-on-revisions coefficient at the forecaster-level against estimated public noise dispersion, proxied by the standard deviation of government revisions to real-time data. Slope of fitted line is -0.046 .

Testable Prediction 4: Error Predictability and Release Frequency

As an additional way to measure signal precision, I consider the frequency with which these different variables are made available to the public. While professional forecasters report predictions in each quarter, some variables are made available at higher frequencies. Specifically the SPF conducts its survey at roughly the middle of each quarter. However, some of the SPF variables are released at a monthly frequency. For instance employment statistics are released on the Friday of each month. The survey asks forecasters to provide a quarterly average of these series. Furthermore, the financial time series are available at a daily frequency. As a result, forecasters have more information pertaining to some x_t at the time that they report their predictions than others. This reduces the effective noise in the lagged public signal.²³ Hence, variables available at higher frequencies should raise the scope for underreaction. Note that this does not preclude overreactive behavior in financial markets as has been readily documented. Here, I simply argue that quarterly (average of daily observations) predictions of a financial variable are better informed by the presence of daily observations through the middle of the quarter when the reported forecast is requested. On the other hand, the

²³ Alternatively, one could suppose that forecasters receive an additional informative public signal for monthly/daily SPF variables.

Figure 6: Error Predictability and Unconditional Volatility

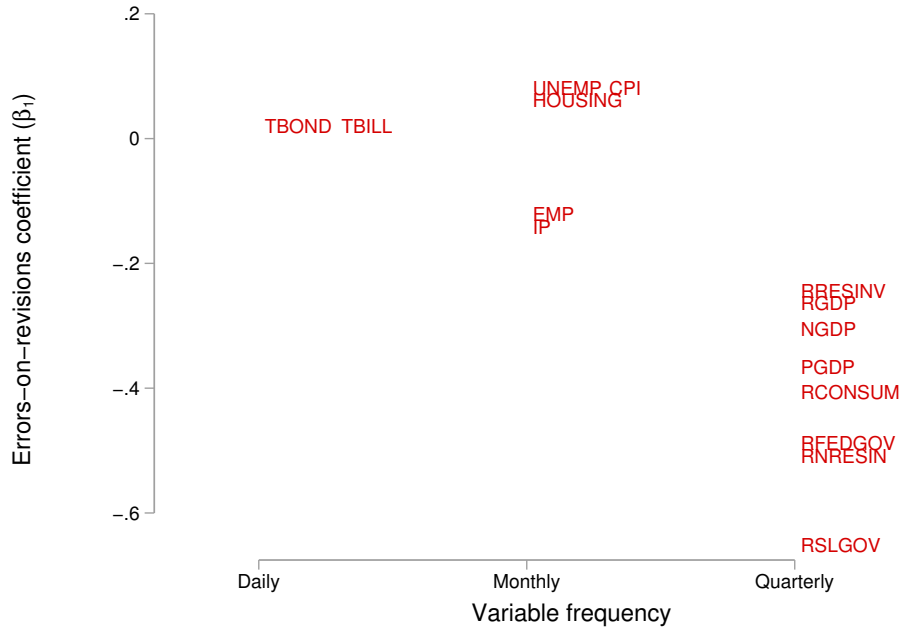

Note: For each SPF variable, the figure plots the estimated errors-on-revisions coefficient at the forecaster-level against estimated unconditional volatility of the state, $\exp(\hat{\phi}_0/2)$. Slope of fitted line is 0.100.

latest information that forecasters have for quarterly variables, such as GDP, is the previous quarter's release and an advance estimate. Since there is additional information available for some variables and not others, and the existence of this additional information depends on the variable frequency, then it follows that there is more scope for underreaction among variables that are available at higher frequencies.

Jointly Testing for Overreaction and Underreaction Channels

As an additional check, I formally test for these channels jointly. For the data to accord with this theory of nonlinear expectations, it should be the case that an interaction of the forecast revision with each of these variables either raises or reduces the extent to which β_1 is negative in the pooled specification (column 1 of Table 1). To complete this exercise, I incorporate two new regressors (and all possible interactions), each capturing a source of either noise or state volatility. As a measure of noise, I select the release frequency explained above. Intuitively, SPF variables available at lower frequencies are inherently less informative and therefore raise the scope for overreaction. For my measure of fundamental volatility, I take a factor analysis approach. Since the latent state and its volatility are unobservable, it is natural to consider an index of the

Figure 7: Error Predictability and Frequency

Note: For each SPF variable, the figure plots the estimated errors-on-revisions coefficient at the forecaster-level against variable's release frequency {Daily, Monthly, Quarterly}.

shared variation among all SPF variables. From this exercise, I obtain a time varying index of what I call fundamental volatility.²⁴

With these two new regressors, I then modify the baseline errors-on-revisions regression (pooling across all SPF variables as in Table 1). In addition to projecting errors on revisions, I also specify the “Noise” variable (from the variable release frequency), the “Fundamental Volatility” (from the constructed index). I also include interactions of each of these with the forecast revision as well as all interactions with each other. The regression results are reported in Table 4.

The first column of the table reproduces the first column of Table 1. The second column of Table 5 reports the fully specified regression while the third column incorporates fixed effects. The relationship of interest remains the extent to which the forecast error and revision are related. Noise and fundamental volatility

²⁴For this analysis, I drop nominal GDP since its components reside in my data set. Furthermore, I exclude CPI due to its shorter available history. For the remaining macroeconomic variables, I compute five-year rolling standard deviations and then estimate underlying principal factors. The results deliver two factors that explain roughly equal amounts of the common variance of the final vintage of SPF variables. Based on the factor loadings, I call the first factor a real residential factor, and the second a real non-residential factor (the residential factor loads highly on housing and real residential investment whereas the second factor does not). While both factors deliver the correct sign in my regression specification, I report the regression that specifies the real non-residential factor as it delivers statistically detectable results. The results are robust to 7- and 10-year window lengths, as well as specifying the real-time vintages.

Table 4: Modified Forecast Error Predictability Panel Regressions

	Forecast Error		
	(1)	(2)	(3)
Revision	-0.317*** (0.050)	-0.165** (0.073)	-0.245*** (0.056)
Revision \times Noise		-0.194** (0.089)	-0.115** (0.055)
Revision \times Fundamental Volatility		0.106** (0.041)	0.095*** (0.022)
Forecaster \times Variable FE	N	N	Y
Quarter FE	N	N	Y
Observations	65,070	58,740	58,740

Note: The table reports estimated coefficients of forecast error predictability across three pooled specifications. The variable *Noise* is equal to 0 if the SPF variable is released at a non-quarterly frequency and 1 otherwise. The *Fundamental Volatility* variable is a time-varying index of fundamental volatility constructed as described in the text. Column (1) reports a simple regression of errors-on-revisions, columns (2) and (3) include the two proxies described, where column (3) includes fixed effects. In addition to the variables reported in the table, Columns (2) and (3) include the proxies individually as well as all of their interactions. Standard errors for forecaster-level regressions are as in Driscoll and Kraay (1998). Data used for estimation come from SPF (1964Q4-2018Q3). *** denotes 1% significance, ** denotes 5% significance, and * denotes 10% significance.

have no statistically detectable relation with the forecast error. In other words, these proxies cannot independently predict forecasters' mistakes. The regression also includes all possible interaction terms between the regressors. The only interaction terms that are statistically significant are those crossed with the forecast revision. Furthermore, the signs of these two interactions are consistent with the expected signs according to my theory of nonlinear expectations. In particular, noise raises the scope for overreactions as evidenced by the negative cross term between the noise proxy and the revision. On the other hand, fundamental volatility reduces the scope for overreaction as seen by the positive coefficients in front the relevant interaction terms.

7 Parameterizing the Stylized Model

Finally, I parameterize the model in Section 5 for real GDP and unemployment. Specifically, I calibrate the public noise dispersion (σ_e), the persistence of the latent state (ρ), and the stochastic volatility parameters ($\phi_0, \phi_1, \sigma_\eta$). I then find the values of \bar{c}_A and σ_v that minimize the distance between the model-simulated and empirical estimates of $\hat{\beta}_1$ and $\hat{\alpha}_1$.

For real GDP and unemployment respectively, I set σ_e equal to the standard deviation of the data revisions made to each variable over the sample period. The data revision is taken to be the difference between the

Table 5: External Parameterization

Parameter	Description	Unemployment	Real GDP
ρ	State persistence	0.98	0.30
σ_e	Standard deviation of public noise	0.07	2.02
ϕ_0	Level of log variance	-0.76	0.14
ϕ_1	Persistence of log variance	0.73	0.92
σ_η	Volatility of log variance	0.69	0.39

Note: The table reports parameterization for unemployment and real GDP. Stochastic volatility parameters $\{\phi_0, \phi_1, \sigma_\eta\}$ are estimated according to the algorithm presented in Kaster and Fruhwirth-Schnatter (2014).

first and final release of the data series. For the remaining parameters, I consider the revised data rather than the real-time data. Intuitively, these series should be more highly correlated with the unobserved latent state (s_t). I then estimate an AR(1) on the revised series and set ρ equal to the estimated AR(1) coefficient. Finally, I collect the squared residuals from this autoregression and estimate $\{\phi_0, \phi_1, \sigma_\eta\}$. Table 5 reports the calibration for each variable.

Finally, I parameterize σ_v and \bar{c}_A by minimizing the distance between the model-implied $\{\alpha_1, \beta_1\}$ from its empirical counterpart. Computationally, this is done as follows. For each simulation, I generate a simulated state variable (s_t) according to the dynamics described in Section 5. I then simulate the lagged public signal, x_{t-1} as well as the contemporaneous private signal y_t^i . Forecasters generate a forecast in each simulated period t according to the loss function described in Section 5. From this simulated panel of forecasters, I construct the errors-on-revisions coefficients. I minimize the distance between the simulated and empirical OLS coefficients by making use of simulated annealing, a global optimization algorithm. The results are reported in Table 6.

The results indicate that real GDP is in fact characterized by more noise than the unemployment rate. The implied signal-to-noise ratio for real GDP is about 0.58 whereas it is 0.98 for unemployment. This is consistent with the intuition of the model as well as the cross-sectional evidence in the previous section: variables that exhibit higher signal-to-noise ratios are precisely those variables for which we observe underreactions.

Furthermore, the upper bound of the cost distribution is higher for real GDP than it is for unemployment. The higher upper support for real GDP is a result of the larger errors made when predicting a noisier variable. These estimates imply that nearly no forecaster opts to use the particle filter to forecast unemployment whereas almost 70% of forecasters choose the particle filter as the preferred model when predicting real GDP. This is consistent with the intuition as real GDP appears to be noisier than unemployment in the data. Hence,

Table 6: Calibration Results

Variable	$\hat{\sigma}_v$	\widehat{c}_A	Implied SNR	Share using PF
Unemployment	0.181	0.989	0.984	0.010
Real GDP	2.092	1.683	0.583	0.685
<i>Share that overreact to real GDP and underreact to unemployment</i>				
Model	0.56			
Data	0.64			

Note: The first two columns of the top panel of the table report estimated coefficients of private signal noise dispersion and upper bound of approximation cost function. The third column reports the implied signal-to-noise ratio while the final column reports the implied share of forecasters making use of the particle filter of the naive Kalman filter. The bottom panel compares the model-implied share of over- and underreactions with the data (for real GDP and unemployment).

forecasters are more likely to incur the cost to adopt a more sophisticated forecast.

Lastly, the stylized model is able to generate a surprisingly similar share of over- and underreactions. Figure 1 reports that about 64% of forecasters in my sample overreact to real GDP while simultaneously underreacting to unemployment. Based on the simple parameterization devised here, the stylized model implies that 56% of forecasters overreact to real GDP and underreact to unemployment.

7.1 Implications for Information Rigidities

What does time-varying volatility coupled with imperfect information imply about interpreting the reduced form coefficient β_1 as an information rigidity? This is a relevant question as some of the recent literature has adopted the reduced form errors-on-revisions regressions to quantify information rigidities.²⁵ Based on my model, it is apparent that β_1 does not cleanly map to the Kalman gain as it does in the scalar linear context. The key intuition of Bayesian filtering, however, still holds, and the optimal weight placed on innovation errors remains a sufficient statistic for capturing the rate of learning. This weight depends on the covariances of the state estimation error and the measurement error. Quantifying the rate of learning, however, is not readily feasible from a projection of errors on revisions.

In fact, from the perspective of this model, the coefficient coming from errors on revisions regressions can reveal misleading insights on the extent of information rigidity. β_1 is positive when the SNR is high. This would typically imply larger information rigidities, however, my model suggests that this implies a higher rate of learning. Furthermore, a negative β_1 arises when signals are less informative. This suggests that the

²⁵See for instance Baker et al. (2020) and Ryngaert (2017).

reduced form coefficients β_1 (and α_1) are limited in what they reveals about information frictions.

7.2 Implications for State Dependence

What does this mean for state dependence? If β_1 and α_1 were to rise in recessions, then the model would imply that the signal to noise ratio is countercyclical and information rigidities fall during economic downturns. If, on the other hand, these coefficients fall, then the signal-to-noise ratio is procyclical and information rigidities actually rise in recessions. CG document evidence indicating that α_1 falls in recessions. They interpret this as a reduction in information rigidities, however, my model would suggest that this implies a *rise* in information rigidities as the signal-to-noise ratio is falling which implies that the system experiences elevated amounts of noise (i.e. information is less precise in recessions). This is an important distinction between my model and the extant literature as it delivers an opposite answer to the question of whether individuals trust their signal more or less in recessions.

However, after performing a similar exercise to that in Table 5 by interacting a quarterly recession indicator with forecast revisions, I find no evidence that β_1 or α_1 changes with the business cycle. I also run this exercise by replacing the recession indicator with revised real GDP growth. It is possible, however, that the signal-to-noise ratio is insensitive to business cycle fluctuations because both the state and the signal experience stochastic volatility. I abstract away from volatility in signal precision, and so there is a limit to what one can glean from this model as it pertains to state dependence of information rigidities.

Nonetheless, one could distinguish between two types of uncertainty: fundamental uncertainty and information uncertainty. The first maps to time varying volatility in the state while the latter arises when signal noise experiences stochastic volatility. There is a literature that stresses the importance of uncertainty shocks. These are often modeled as fundamental uncertainty shocks, however, shocks to information precision also studied in the literature.²⁶ According to this model, the state dependence of β_1 and α_1 depend on the signal-to-noise ratio which in turn depends on how fundamental vs. information uncertainty evolve over the business cycle. If both rise in recessions, then is possible that the signal-to-noise ratio is acyclical thereby rendering β_1 and α_1 roughly constant over the cycle as well.

²⁶For instance, [Dun Jia \(2016\)](#)

8 Conclusion

This paper shows that a noisy information model that incorporates time-varying volatility in the evolution of the latent state can generate error predictability at the forecaster-level. Several recent studies have explained error predictability with a model of non-rational expectations. Here, I show that this empirical fact can arise among rational forecasters attempting to predict a nonlinear state. Forecasters make unavoidable approximation errors when formulating expectations about the underlying state. These approximation errors can jointly deliver perceived under- and overreactions among forecasters. On the other hand, most behavioral theories can explain only one or the other. To this end, violations of error orthogonality are best understood as evidence against linear rational expectations.
